ABSTRACT

Objective: Diagnosis of supratentorial space occupying lesion is a frequent dilemma in neurosurgical practice. MR spectroscopy that is an advanced MR imaging sequence can prove to be decisive in such cases. The objective of the study is to determine diagnostic accuracy of MRS in differentiating supra-tentorial brain space occupying lesions taking histopathology as gold standard

Material and Methods: The cross-sectional study was conducted at Department of Neurosurgery, Jinnah Postgraduate Medical Centre, Karachi from August 2018 to July 2019. A calculated sample size of 156 patients aged between 18-50 years after informed consent. All patients underwent MR Spectroscopy pre-operatively. Surgery was performed and histopathological findings were compared with spectroscopic findings.

Results: The average age of the patients was 32.41 ± 10.02 years. There were 84 (53.84%) males and 72 (46.15%) females. The sensitivity of MRS was 90.69% with a specificity of 97.34%.

Conclusion: MR Spectroscopy is an accurate diagnostic tool for establishing pre-operative differentiation between neoplastic and inflammatory lesion. It should be performed in all cases where contrast MRI is inconclusive in establishing the diagnosis.

Keywords: Magnetic Resonance Spectroscopy, Brain Abscess, Supratentorial lesion, Brain Tumor.

Abbreviations: MRS: Magnetic Resonance Spectroscopy. SOL: Space Occupying Lesion.

INTRODUCTION

Diagnosis of supratentorial space occupying lesion (SOL) in brain is a frequent dilemma in neurosurgical practice.1 These lesions may vary from simple arachnoid cysts requiring nothing but observation to brain abscess requiring emergency surgery. Inflammatory brain lesions are 50 times less common than neoplasm2,3 and account for only 1-2 % of all brain SOL in the west. However, its incidence is as high as 8% in the developing countries.4 An early diagnosis of SOL is of utmost importance in order to plan surgical intervention or conservative management.

Neuroradiology plays a pivotal role in the diagnosis of such SOL. These may include CT scan or MRI. Recent advancements in MRI scanners have led to the availability of advanced sequences such as Diffusion weighted images. Magnetic Resonance Spectroscopy (MRS) is another state of the art technique which presents processed data as amplitude by frequency plots rather than images.5 The important brain metabolites analyzed and plotted on spectrum are choline containing compounds (Cho) at 3.2 ppm, Creatine and Phosphocreatine (Cr) at 3.0 ppm, N-acetyl aspartate (NAA) at 2.02 ppm, Lactate (Lac) 1.32 ppm, Lipids at 0.9–1.5 ppm and Myo-inositol at 3.56 ppm.6-9 Other metabolites include, Glutamine, Glutamate, Leucine and Alanine.10,11 These levels of metabolites have their own significance. For example, the NAA is a marker of neuronal integrity, Cho is...
linked to cell membrane turnover, Cr reflects energy storage and myo-inositol is a glial marker. Lipids and Lactate are absent in normal brain and are inflammatory markers of necrosis and anaerobic metabolism respectively.\(^9\)

MRS has already been used for studying developmental behavior of human brain, hypoxic brain injury in neonates, congenital metabolic disorders, seizure disorders, brain tumors, neuro-degenerative and demyelinating diseases.\(^12\)

MRS is primarily used to differentiate neoplastic lesions from inflammatory ones. The metabolites show a characteristic pattern different with pathologies. These are either interpreted as their peak levels or as a ratio. In brain abscess, NAA, Cho and Cr are typically absent because there is no normal neuron within the cavity. However, Lactate, lipids, amino acids including Leucine and alanine peaks are present.\(^12\) Neoplastic lesions show increased Cho due to increased cellular turnover and decreased NAA levels. Cho/Cr and Cho/NAA ratios are also increased.\(^13\)

MRS is a novel technique and therefore literature is scarce. The diagnostic accuracy of MRS varies from 90% to 94% in different studies.\(^13\) The sensitivity and specificity varies from 80 to 98% and 70 to 78% respectively.\(^14\)-\(^17\) The studies conducted so far have included both supra and infra tentorial brain SOL. Presence of lesions near the bone and post fossa may augment the biochemical assay and affect the final diagnosis. Both national and international data is scarce on the comparison based findings related to MRS and Histopathology. This study will therefore focus on supra-tentorial brain SOL in order to determine diagnostic accuracy of MRS.

MATERIAL AND METHODS

Study Design and Setting
The Cross-sectional study was conducted at Department of Neurosurgery, Jinnah Postgraduate Medical Centre, Karachi from August 2018 to July 2019.

Sampling
Sample Size was calculated using a sample size calculator for sensitivity and specificity. Taking sensitivity as 90.16%\(^14\) with precision of 9.5% and specificity as 70%\(^15\) with precision of 10%, at 95% confidence interval with a prevalence of 17%;\(^15\) the sample size was calculated as 156 patients. Non-probability consecutive sampling technique was used to collect data.

Inclusion Criteria
Patients included of either gender, aged 18 to 50 years who consent to participate in the study with newly diagnosed Supratentorial Brain SOL appearing hypo or hyper-intense on MRI with post contrast enhancement.

Exclusion Criteria
Pregnant females, patients with any previous intracranial surgery, multiple SOLs on initial MRI, diagnosed neoplasm of any other region of body and bleed within the SOL on initial MRI were excluded from the study.

Data Collection and Data Analysis
Data was collected on a pre-designed questionnaire data statistical analysis was done using SPSS version - 23. MRS and histological findings were tabulated using 2x2 tables. Sensitivity, specificity, positive and negative predictive values were calculated.

RESULTS

Age Range
A total of 156 patients were included in this study. The average age of the patients was 32.41 ± 10.02 years (range 18 – 50 years).

Gender Distribution
There were 84 (53.84%) male and 72 (46.15%) female.

Clinical Presentation
The mean height of patients was 1.51 ± 0.21 m, the mean weight was 57.96 ± 10.33 kg and the mean BMI of patients was 25.59 ± 4.93 kg/m\(^2\). The average duration of symptoms was 8.41 ± 3.79 weeks. Altered level of consciousness was the most common symptom in our patients (81.4%) followed by fever (19.9%) and history of ENT infection (10.9%).

Sensitivity & Specificity
The sensitivity of MRS was 90.69% with a specificity of 97.34%. The Positive predicted value of MRS
calculated as 92.85% and Negative predictive value as 96.49% (Table 1 – 3). The agreement between MR spectroscopic and histological findings was measured as 0.887 with approximate significance of < 0.005. The diagnostic accuracy of MRS was calculated as 95.51% with 39 true positive and 110 true negative results.

### Stratification Analysis

Stratification analysis was performed with respect to effect modifiers. This showed that the sensitivity of MRS in males (86.95%) was less than females (95.0%). It was also lower in patients aged between 31 – 40 years (87.50%) compared to age groups 18 – 30 (91.30%) and 41 – 50 (91.67%). The sensitivity was also halved if the duration of symptoms was more than 8 weeks. Low BMI (< 20.0 kg/m²) also reduced sensitivity to 66.67%.

### DISCUSSION

MR Spectroscopy provides chemical analysis of cerebral lesion that aids in establishing non-invasive diagnosis. It is being used for differentiating cerebral inflammatory lesions from neoplastic lesions. The diagnosis was based on amount of certain chemical marker on spectroscopy and their ratios.

Choline (Cho) levels of 2.15 mmol/l and Choline to NAA ratio above 1 is considered as diagnostic of neoplastic lesion.14,18 However, these values are not absolute and vary a great deal in the literature. Moreover, different cut off values of these makers may affect the diagnostic accuracy of MRS.

Additionally, these values may also be used to differentiate low and high grade neoplasm with Mean Cho value of 1.65 ± 1.03 mmol/l in low-grade Gliomas and 2.36 ± 1.15 mmol/l in high-grade astrocytoma.14 Similarly, Choline to Creatinine ratio in low-grade Gliomas was 2.98 ± 2.73 whereas in high-grade Gliomas it was 3.93 ± 3.33. It was reported in a study that the former was 1.26 ± 0.38 and the latter was 2.11 ± 0.93.19 another study suggested the cut off value to differentiate between the two grades as 1.56.20 On the other hand, a study concluded this value as 1.84 ± 1.22 for metastatic lesions against 3.92 ± 3.31 for high grade Gliomas.

Interpretation of the results is also be falsified by the contents. For instance, inflammatory metabolites can be accumulated in necrotic high-grade Gliomas resulting in reduced levels of choline in addition to NAA and creatine. It also resulted in tall lipid/lactate peak. On the contrary, invasive infections (e.g. fungus) can produce high level of choline and lower the levels of creatinine and NAA.21

The mean age of presentation in our study was similar to previously conducted local studies. Our patients were predominantly males; this was also similar to other studies.14-16

Our study showed sensitivity of 90.69% which is similar to previously conducted studies which ranged from 79% to 100%.14-16,22-26 The specificity reported in the literature is 74% to 100%.14-16,22-26 However, specificity calculated in our study (97.34%) was slightly higher than some studies including one conducted at our center in the past.16 This may be attributed to the fact that our study only included patients with supra-tentorial lesions whereas, other studies have included both supra and infra-tentorial lesion. Since the compact bony anatomy in the posterior fossa hinders the spectroscopic signal

estimation, that may affect the specificity of the test. Another possible explanation is the difference of placement of voxels and interpretation of results which may have improved over time. Correct Voxel placement of utmost importance in accuracy of the diagnosis. The prospect of including viable proliferating tumor in the spectroscopic volume is improved by placing it on the leading edge of enhancing lesion thus minimizing the possibility of necrotic focus.15

Moreover, this study was conducted on adult patients between ages 18 and 50 years only however, previous studies included both adults and children. Nonetheless, the diagnostic accuracy of our study was similar to previously conducted local studies.14-16

Limitations of the Study

This study was conducted on patients from a single institution. Although the sample size was adequate, but inflammatory lesions were considerably lesser than the neoplastic lesions. This may be attributed to the fact that many of the inflammatory lesions are treated medically.

The results were based on single voxel technique and may have significant inter-observer interpretation bias compared to multi-voxel technique. The diagnostic accuracy of MRS was based on the overall interpretation of the biochemical markers. However, individual biomarkers and their ratios may have different diagnostic accuracy.

Implications for Future Research

Future studies may be conducted on the basis of individual biochemical analysis for the diagnosis of inflammatory vs. neoplastic lesions. Moreover, these values may also be investigated for differentiating different types of tumors and their grades. Differentiation between causes of inflammatory lesions such as tuberculomas or fungus may be useful fronts for future research. Different cut off absolute values of biochemical markers may be studied and their effect on overall diagnostic accuracy.

CONCLUSION

This study concluded the high diagnostic accuracy of MRS for inflammatory and neoplastic lesions. MRS therefore may be used as non-invasive investigation for differentiating neoplasm from inflammatory lesions. However, in cases where differentiation is difficult, the implication of MRS becomes more profound in establishing pre-operative diagnosis and early treatment.
